

# FACTORBASE : SQL for Learning A Multi-Relational Graphical Model

Oliver Schulte, Zhensong Qian  
Simon Fraser University, Canada  
{oschulte,zqian}@sfu.ca

**Abstract**—We describe FACTORBASE, a new SQL-based framework that leverages a relational database management system to support multi-relational model discovery. A multi-relational statistical model provides an integrated analysis of the heterogeneous and interdependent data resources in the database. We adopt the BayesStore design philosophy: statistical models are stored and managed as first-class citizens inside a database [30]. Whereas previous systems like BayesStore support multi-relational inference, FACTORBASE supports multi-relational learning. A case study on six benchmark databases evaluates how our system supports a challenging machine learning application, namely learning a first-order Bayesian network model for an entire database. Model learning in this setting has to examine a large number of potential statistical associations across data tables. Our implementation shows how the SQL constructs in FACTORBASE facilitate the fast, modular, and reliable development of highly scalable model learning systems.

## I. INTRODUCTION

Data science brings together ideas from different fields for extracting value from large complex datasets. The system described in this paper combines advanced analytics from multi-relational or *statistical-relational* machine learning (SRL) with database systems. The power of combining machine learning with database systems has been demonstrated in several systems [11], [15], [3]. The novel contribution of FACTORBASE is supporting machine learning for *multi-relational* data, rather than for traditional learning where the data are represented in a *single* table or data matrix. We discuss new challenges raised by multi-relational model learning compared to single-table learning, and how FACTORBASE solves them using the resources of SQL (Structured Query Language). The name FACTORBASE indicates that our system supports learning factors that define a log-linear multi-relational model [14]. Supported new database services include constructing, storing, and transforming complex statistical objects, such as factor-tables, cross-table sufficient statistics, parameter estimates, and model selection scores.

Multi-relational data have a complex structure, that integrates heterogeneous information about different types of entities (customers, products, factories etc.) and different types of relationships among these entities. A statistical-relational model provides an integrated statistical analysis of the heterogeneous and interdependent complex data resources maintained by the database system. Statistical-relational models have achieved state-of-the-art performance in a number of application domains, such as natural language processing,

ontology matching, information extraction, entity resolution, link-based clustering, query optimization, etc. [4], [20], [8]. Database researchers have noted the usefulness of statistical-relational models for knowledge discovery and for representing uncertainty in databases [28], [30]. They have developed a system architecture where statistical models are stored as first-class citizens *inside a database*. The goal is to seamlessly integrate query processing and statistical-relational inference. These systems focus on inference *given* a statistical-relational model, not on *learning* the model from the data stored in the RDBMS. FACTORBASE complements the in-database probabilistic inference systems by providing an in-database probabilistic model learning system.

## A. Evaluation

We evaluate our approach on six benchmark databases. For each benchmark database, the system applies a state-of-the-art SRL algorithm to construct a statistical-relational model. Our experiments show that FACTORBASE pushes the scalability boundary: Learning scales to databases with over  $10^6$  records, compared to less than  $10^5$  for previous systems. At the same time it is able to discover more complex cross-table correlations than previous SRL systems. We report experiments that focus on two key services for an SRL client: (1) Computing and caching sufficient statistics, (2) computing model predictions on test instances. For the largest benchmark database, our system handles 15M sufficient statistics. SQL facilitates block-prediction for a set of test instances, which leads to a 10 to 100-fold speedup compared to a simple loop over test instances.

## B. Contributions

FACTORBASE is the first system that leverages relational query processing for learning a multi-relational log-linear graphical model. Whereas the in-database design philosophy has been previously used for multi-relational inference, we are the first to adapt it for multi-relational model structure learning. Pushing the graphical model inside the database allows us to *use SQL as a high-level scripting language for SRL*, with the following advantages.

- 1) Extensibility and modularity, which support rapid prototyping. SRL algorithm development can focus on statistical issues and rely on a RDBMS for data access and model management.

- 2) Increased scalability, in terms of both the size and the complexity of the statistical objects that can be handled.
- 3) Generality and portability: standardized database operations support “out-of-the-box” learning with a minimal need for user configuration.

### C. Paper Organization

We provide an overview of the system components and flow. For each component, we describe how the component is constructed and managed inside an RDBMS using SQL scripts and the SQL view mechanism. We show how the system manages sufficient statistics and test instance predictions. The evaluation section demonstrates the scalability advantages of in-database processing. The intersection of machine learning and database management has become a densely researched area, so we end with an extensive discussion of related work.

## II. BACKGROUND ON STATISTICAL-RELATIONAL LEARNING

We review enough background from statistical-relational models and structure learning to motivate our system design. The extensive survey by Kimmig *et al.* [14] provides further details. The survey shows that SRL models can be viewed as log-linear models based on par-factors, as follows.

### A. Log-linear Template Models for Relational Data

Par-factor stands for “parametrized factor”. A par factor represents an interaction among parametrized random variables, or par-RVs for short. We employ the following notation for par-RVs [14, 2.2.5]. Constants are expressed in lower-case, e.g. *joe*, and are used to represent entities. A type is associated with each entity, e.g. *joe* is a person. A first-order variable is also typed, e.g. *Person* denotes some member of the class of persons. A functor maps a tuples of entities to a value. We assume that the range of possible values is finite. An *atom* is an expression of the form  $r(\tau_1, \dots, \tau_a)$  where each  $\tau_i$  is either a constant or a first-order variable. If all of  $\tau_1, \dots, \tau_a$  are constants,  $r(\tau_1, \dots, \tau_a)$  is a *ground atom* or random variable (RV), otherwise a *first-order atom* or a **par-RV**. A par-RV is instantiated to an RV by grounding, i.e. substituting a constant of the appropriate domain for each first-order variable.

A **par-factor** is a pair  $\Phi = (A, \phi)$ , where  $A$  is a set of par-RVs, and  $\phi$  is a function from the values of the par-RVs to the non-negative real numbers.<sup>1</sup> Intuitively, a grounding of a par-factor represents a set of random variables that interact with each other locally. SRL models use *parameter tying*, meaning that if two groundings of the same par-factor are assigned the same values, they return the same factor value. A set of parfactors  $\mathcal{F}$  defines a joint probability distribution over the ground par-RVs as follows. Let  $\mathcal{I}(\Phi_i)$  denote the set of *all* ground par-RVs in par-factor  $\Phi_i$ . Let  $\mathbf{x}$  be a joint assignment of values to all ground random variables. Notice that this assignment determines the values of all ground atoms. An assignment  $\mathbf{X} = \mathbf{x}$  is therefore *equivalent to a single*

*database instance*. The probability of a database instance is given by the log-linear equation [14, Eq.7]:

$$P(\mathbf{X} = \mathbf{x}) = \frac{1}{Z} \prod_{\Phi_i \in \mathcal{F}} \prod_{\mathbf{A} \in \mathcal{I}(\Phi_i)} \phi_i(\mathbf{x}_{\mathbf{A}}) \quad (1)$$

where  $\mathbf{x}_{\mathbf{A}}$  represents the values of those variables in  $\mathbf{A}$  that are necessary to compute  $\phi_i$ . Equation 1 can be read as follows.

- 1) Instantiate all parfactors with all possible constants.
- 2) For each ground par-factor, apply the values specified by the joint assignment  $\mathbf{X} = \mathbf{x}$ , and compute the corresponding factor term.
- 3) Multiply all the factors together, and normalize the product.

Typically the number of ground par-RVs  $\mathcal{I}(\Phi_i)$  will be very large. Equation 1 can be evaluated, without enumerating the ground par-factors, as follows.

- 1) For each par-factor, for each possible assignment of values, find the number of ground factors with that assignment of values.
- 2) Raise the factor value for that assignment to the number of instantiating factors.
- 3) Multiply the exponentiated factor values together, and normalize the product.

The number 2) of ground factors with the same assignment of values is known as a **sufficient statistic** of the log-linear model.

### B. Examples

SRL has developed a number of formalisms for describing par-factors [14]. First-order probabilistic graphical models are popular both within SRL and the database community [14], [30]. The model structure is defined by edges connecting par-RVs. For instance, a **parametrized Bayesian network structure** is a directed acyclic graph whose nodes are par-RVs. Figure 3 shows a Bayesian network for a University domain. We use the university example as a toy running example

<sup>1</sup> A par-factor can also include constraints on possible groundings.

Figure 3. (a) Bayesian network for the University domain. We omit the *Registered* relationship for simplicity. The network was learned from the University dataset [24]. (b) Conditional Probability table  $Capa(P,S)_{CPT}$ , for the node  $Capa(P,S)$ . Only value combinations that occur in the data are shown. This is an example of a factor table. (c) Contingency Table  $Capa(P,S)_{CT}$  for the node  $Capa(P,S)$  and its parents. Both CP and CT tables are stored in an RDBMS.

throughout the paper. The schema for the university domain is given in Figure 1. This schema features only one relationship for simplicity; FACTORBASE learns a model for any number of relationships. While we describe FACTORBASE abstractly in terms of par-factors, for concreteness we illustrate it using Bayesian networks. The system takes as input a database instance like that shown in Figure 2, and produces as output a graphical model like that shown in Figure 3.

A par-factor in a Bayesian network is associated with a **family** of nodes [14, Sec.2.2.1]. A family of nodes comprises a child node and all of its parents. For example, in the BN of Figure 3, one of the par-factors is associated with the par-RV set  $A = \{Capa(P,S), Salary(P,S), RA(P,S)\}$ . For the database instance of Figure 2, there are  $3 \times 3 = 9$  possible factors associated with this par-RV, corresponding to the Cartesian product of 3 professors and 3 students. The value of the factor  $\phi$  is a function from an assignment of family node values to a non-negative real number. In a Bayesian network, the factor value represents the conditional probability of the child node value given its parent node values. These conditional probabilities are typically stored in a table as shown in Figure 3(b). This table represents therefore the function  $\phi$  associated with the family par-factor. Assuming that all par-RVs have finite domains, a factor can always be represented by a **factor table** of the form Figure 3(b): there is a column for each par-RV in the factor, each row specifies a joint assignment of values to a par-RV, and the factor column gives the value of the factor for that assignment (cf. [14, Sec.2.2.1]).

The sufficient statistics for the  $Capa(P,S)$  family can be represented in a contingency table as shown in Figure 3(c). For example, the first row of the contingency table indicates

that the conjunction

$Capa(P,S) = n/a, Salary(P,S) = n/a, RA(P,S) = F$  is instantiated 203 times in the University database (publicly available at [24]). This means that for 203 professor-student pairs, the professor did not employ the student as an RA (and therefore the salary and capability of this RA relationship is undefined or  $n/a$ ).

### C. SRL Structure Learning

Algorithm 1 shows the generic format of a statistical-relational structure learning algorithm (adapted from [14]). The instantiation of procedures in lines 2, 3, 5 and 8 determines the exact behavior of a specific learning algorithm. The structure algorithm carries out a local search in the hypothesis space of graphical relational models. A set of candidates is generated based on the current model (line 3), typically using a search heuristic. For each candidate model, parameter values are estimated that maximize a model selection score function chosen by the user (line 5). A model selection score is computed for each model given the parameter values, and the best-scoring candidate model is selected (line 7). We next discuss our system design and how it supports model discovery algorithms that follow the outline of Algorithm 1. Figure 4 outlines the system components and dependencies among them.

---

#### Algorithm 1: Structure learning algorithm

---

**Input:** Hypothesis space  $\mathcal{H}$  (describing graphical models), training data  $\mathcal{D}$  (assignments to random variables), scoring function score  $(\cdot, \mathcal{D})$

**Output:** A graph structure  $G$  representing par-factors.

```

1:  $G \leftarrow \emptyset$ 
2: while CONTINUE( $G, \mathcal{H}, \text{score}(\cdot, \mathcal{D})$ ) do
3:    $\mathcal{R} \leftarrow \text{REFINECANDIDATES}(G, \mathcal{H})$ 
4:   for each  $R \in \mathcal{R}$  do
5:      $R \leftarrow \text{LEARNPARAMETERS}(R, \text{score}(\cdot, \mathcal{D}))$ 
6:   end for
7:    $G \leftarrow \text{argmax}_{G' \in \mathcal{R} \cup \{G\}} \text{score}(G', \mathcal{D})$ 
8: end while
9: return  $G$ 

```

---

### III. THE RANDOM VARIABLE DATABASE

Statistical-relational learning requires various metadata about the par-RVs in the model. These include the following.

**Domain** the set of possible values of the par-RV.

**Types** Pointers to the first-order variables in the par-RV.

**Data Link** Pointers to the table and/or column in the input database associated with the par-RV.

The metadata must be machine-readable. Following the in-database design philosophy, we store the metadata in tables so that an SRL algorithm can query it using SQL. The schema analyzer uses an SQL script that queries key constraints in the system catalog database and *automatically* converts them into metadata stored in the random variable database VDB. In contrast, existing SRL systems require users to

Figure 4. System Flow. All statistical objects are stored as first-class citizens in a DBMS. Objects on the left of an arrow are utilized for constructing objects on the right. Statistical objects are constructed and managed by different modules, shown as boxes.

TABLE I. TRANSLATION FROM ER DIAGRAM TO PAR-RVS

ER Diagram	Example	par-RV equivalent
Entity Set	Student, Course	$\mathbb{S}, \mathbb{C}$
Relationship Set	RA	$RA(\mathbb{P}, \mathbb{S})$
Entity Attributes	intelligence, ranking	$Intelligence(\mathbb{S}), Ranking(\mathbb{S})$
Relationship Attributes	capability, salary	$Capability(\mathbb{P}, \mathbb{S}), Salary(\mathbb{P}, \mathbb{S})$

specify information about par-RVs and associated types. Thus FACTORBASE utilizes the data description resources of SQL to facilitate the “setup task” for relational learning [29]. Due to space constraints, we do not go into the details of the schema analyzer. Instead, we illustrate the general principles with the ER diagram of the University domain (Figure 1). The Appendix provides a full description with MySQL script.

The translation of an ER diagram into a set of functors converts each element of the diagram into a functor, except for entity sets and key fields [10]. Table I illustrates this translation. In terms of database tables, attribute par-RVs correspond to *columns*. Relationship par-RVs correspond to *tables*, not columns. Including a relationship par-RV in a statistical model allows the model to represent uncertainty about whether or not a relationship exists between two entities [14]. The values of descriptive attributes of relationships are undefined for entities that are not related. We represent this by introducing a new constant  $n/a$  in the domain of a relationship attribute [18]; see Figure 5 (right). Table II shows the schema for some of the tables that store metadata for each relationship par-RV, as follows. par-RV and FO-Var are custom types.

**Relationship** The associated input data table.

**Relationship\_Attributes** Descriptive attributes associated with the relationship and with the entities involved.

**Relationship\_FOVariables** The first-order variables contained in each relationship par-RV.<sup>2</sup>

TABLE II. SELECTED TABLES IN THE VARIABLE DATABASE SCHEMA.

Table Name	Column Names
Relationship	RVarID: par-RV, TABLE_NAME: string
Relationship_Attributes	RVarID: par-RV, AVarID: par-RV, FO-ID: FO-Var
Relationship_FOvariables	RVarID: par-RV, FO-ID: FO-Var, TABLE_NAME: string

While we have described constructing the variable database for an ER model, different structured data models can be

<sup>2</sup>The schema assumes that all relationships are binary.

```
1 select * from `AttributeColumns`;
2 select * from `Domain`;
```

represented by an appropriate first-order logic vocabulary [14], that is, an appropriate choice of functors. For example, in a star schema, facts can be represented in the form  $f(\mathbb{D}_1, \dots, \mathbb{D}_k)$ , where the first-order variable  $\mathbb{D}_i$  ranges over the primary key of dimension table  $i$ . Attributes of dimension  $i$  can be represented by a unary functor  $a(\mathbb{D}_i)$ . FACTORBASE can perform structure learning for different data models after the corresponding data format has been translated into the VDB format.

#### IV. THE COUNT MANAGER

The **count database CDB** stores a set of *contingency tables*. Contingency tables represent sufficient statistics as follows [19]. Consider a fixed list of par-RVs. A **query** is a set of (*variable = value*) pairs where each value is of a valid type for the variable. The **result set** of a query in a database  $\mathcal{D}$  is the set of instantiations of the logical variables such that the query evaluates as true in  $\mathcal{D}$ . For example, in the database of Figure 2 the result set for the query  $RA(\mathbb{P}, \mathbb{S}) = T, Capability(\mathbb{P}, \mathbb{S}) = 3, Salary(\mathbb{P}, \mathbb{S}) = high$  is the singleton  $\{\langle jack, oliver \rangle\}$ . The **count** of a query is the cardinality of its result set.

Every set of par-RVs  $\mathbf{V} \equiv \{V_1, \dots, V_n\}$  has an associated **contingency table (CT)** denoted by  $CT(\mathbf{V})$ . This is a table

with a row for each of the possible assignments of values to the variables in  $V$ , and a special integer column called *count*. The value of the *count* column in a row corresponding to  $V_1 = v_1, \dots, V_n = v_n$  records the count of the corresponding query. Figure 3(b) shows a contingency table for the par-RVs  $RA(\mathbb{P}, \mathbb{S})$ ,  $Capability(\mathbb{P}, \mathbb{S})$ ,  $Salary(\mathbb{P}, \mathbb{S})$ . The **contingency table problem** is to compute a contingency table for par-RVs  $V$  and an input database  $\mathcal{D}$ .

*SQL Implementation With Metaqueries.* We describe how the contingency table problem can be solved using SQL. This is relatively easy for a *fixed* set of par-RVs; the challenge is a general construction that works for different sets of par-RVs. For a fixed set, a contingency table can be computed by an SQL `count(*)` query of the form

```
CREATE VIEW CT-table(<VARIABLE-LIST>) AS
SELECT COUNT(*) AS count, <VARIABLE-LIST>
FROM TABLE-LIST
GROUP BY VARIABLE-LIST
WHERE <Join-Conditions>
```

FACTORBASE uses SQL itself to construct the count-conjunction query. We refer to this construction as an **SQL metaquery**. We represent a `count(*)` query in four kinds of tables: the *Select*, *From*, *Where* and *Group By* tables. Each of these tables lists the entries in the corresponding `count(*)` query part. Given the four metaquery tables, the corresponding SQL `count(*)` query can be easily constructed and executed in an application to construct the contingency table. Given a list of par-RVs as input, the metaquery tables are constructed as follows from the metadata in the database *VDB*.

**FROM LIST** Find the tables referenced by the par-RV's. A par-RV references the entity tables associated with its first-order variables (see *VDB.Relationship\_FOvariables*). Relational par-RV's also reference the associated relationship table (see *VDB.Relationship*).

**WHERE LIST** Add join conditions on the matching primary keys of the referenced tables in the *WHERE* clause. The primary key columns are recorded in *VDB*.

**SELECT LIST** For each attribute par-RV, find the corresponding column name in the original database (see *VDB.AttributeColumns*). Rename the column with the ID of the par-RV. Add a *count* column.

**GROUP BY LIST** The entries of the *Group By* table are the same as in the *Select* table without the *count* column.

Figure 6 shows an example of a metaquery for the university database. This metaquery defines a view that in turn defines a contingency table for the random variable list associated with the relationship table *RA*. This list includes the entity attributes of professors and of students, as well as the relationship attributes of the *RA* relationship. The Bayesian network of Figure 3 was learned from this contingency table. The contingency table defined by the metaquery of Figure 6 contains only rows where the value of *RA* is true. The Möbius Virtual Join [25] can be used to extend this contingency table to include counts for when *RA* is false, like the table shown in Figure 3(c).

Metaqueries	Entries
CREATE VIEW Select_List AS SELECT RVarID, CONCAT('COUNT(*) as "count"') AS Entries FROM VDB.Relationship UNION DISTINCT SELECT RVarID, AVarID AS Entries FROM VDB.Relationship_Attributes;	COUNT(*) as "count" 'Popularity(P)' 'Teachingability(P)' 'Intelligence(S)' 'Ranking(S)'
CREATE VIEW From_List AS SELECT RVarID, CONCAT('@database@.', TABLE_NAME) AS Entries FROM VDB.Relationship_FOvariables UNION DISTINCT SELECT RVarID, CONCAT('@database@.', TABLE_NAME) AS Entries FROM VDB.Relationship;	@database@.prof AS P  @database@.student AS S  @database@.RA AS 'RA'
CREATE VIEW Where_List AS SELECT RVarID, CONCAT(RVarID, '.', COLUMN_NAME, ' = ', FO-ID, '.', REFERENCED_COLUMN_NAME) AS Entries FROM VDB.Relationship_FOvariables;	'RA'.p_id = P.p_id  'RA'.s_id = S.s_id

Figure 6. Example of metaquery results based on university database and the par-RV metadata (Table II).

## V. THE MODEL MANAGER

The Model Manager provides two key services for statistical-relational structure learning: 1) Estimating and storing parameter values (line 5 of Algorithm 1). 2) Computing one or more model selection scores (line 7 of Algorithm 1). FACTORBASE uses a *store+score* design for these services, which is illustrated in Figure 7. A **model structure table** represents a candidate model. When a candidate model structure is inserted, a view uses the sufficient statistics from a contingency table to compute a table of parameter values. Another view uses the parameter values and sufficient statistics together to compute the score for the candidate model.

Figure 7. Dependencies Among Key Components of the Model Manager.

### A. The MDB Schema

The relational schema for the Models Database is shown in Table III. The `@par-RVID@` parameter refers to the ID of a par-RV, for instance *Capability*( $\mathbb{P}, \mathbb{S}$ ). The model manager stores a set of factor tables (cf. Section II-B). In a graphical model, each factor is defined by the local topology of the model template graph. For concreteness, we illustrate how factor tables can be represented for Bayesian networks. The graph structure can be stored straightforwardly in a database table *BayesNet* whose columns are *child* and *parent*. The table entries are the IDs of par-RVs. For each node, the *MDB* manages a conditional probability table. This is a factor table

TABLE III. THE MAIN TABLES IN THE MODELS DATABASE *MDB*. FOR A BAYESIAN NETWORK, THE *MDB* STORES ITS STRUCTURE, PARAMETER ESTIMATES, AND MODEL SELECTION SCORES.

BayesNet(child:par-RV,parent:par-RV)
@par-RVID@_CPT(@par-RVID@:par-RV,parent <sub>1</sub> :par-RV, . . . , parent <sub>k</sub> :par-RV,cp:real)
Scores(child:par-RV,loglikelihood:real,#par:int,aic:real)

that represents the factor associated with the node's family (see Figure 3(b)). In a Bayesian network, model selection scores are decomposable. This means that there is a local score associated with each family, such that the total score for the BN model is the sum of the local scores. For each family, the local score is stored in the *Scores* table indexed by the family's child node.

### B. Parameter Manager

Deriving predictions from a model requires estimating values for its parameters. Maximizing the data likelihood is the basic parameter estimation method for Bayesian networks. The maximum likelihood estimates equal the observed frequency of a child value given its parent values.

*SQL Implementation With Natural Join.* Given the sufficient statistics in a contingency table, a conditional probability table containing the maximum likelihood estimates can be computed by aggregation using SQL as in the example below.

```
SELECT count/temp.parent_count as CP,
capability(P,S), RA(P,S), salary(P,S)
FROM capability(P,S)_CT
NATURAL JOIN
(SELECT sum(Count) as parent_count,
RA(P,S), salary(P,S)
FROM capability(P,S)_CT
GROUP BY RA(P,S), salary(P,S) ) as temp
```

### C. Model Score Computation

A typical model selection approach is to maximize the likelihood of the data, balanced by a penalty term. For instance, the Akaike Information Criterion (AIC) is defined as follows

$$AIC(G, \mathcal{D}) \equiv \ln(P_{\hat{G}}(\mathcal{D})) - \#par(G)$$

where  $\hat{G}$  is the BN  $G$  with its parameters instantiated to be the maximum likelihood estimates given the database  $\mathcal{D}$ , and  $\#par(G)$  is the number of free parameters in the structure  $G$ . The number of free parameters for a node is the product of (the possible values for the parent nodes)  $\times$  (the number of the possible values for the child node -1). Given the likelihood and the number of parameters, the AIC column is computed as  $AIC = \loglikelihood - \#par$ . Model selection scores other than AIC can be computed in a similar way given the model likelihood and number of parameters.

1) *Parameter Number Computation:* To determine the number of parameters of the child node @parVar-ID@, the number of possible child and parent values can be found from the *VDB.Domain* table in the Random Variable Database.

2) *Likelihood Computation:* As explained in Section II-A, the log-likelihood can be computed by multiplying the instantiation counts of a factor by its value. Assuming that instantiation counts are represented in a contingency table and factor values in a factor table, this multiplication can be elegantly performed using the Natural Join operator. For instance, the log-likelihood score associated with the *Capability*( $\mathbb{P}, \mathbb{S}$ ) family is given by the SQL query below. The aggregate computation in this short query illustrates how well SQL constructs support complex computations with structured objects.

```
SELECT Capability(P,S), SUM
(MDB.Capability(P,S)_CPT.cp *
CDB.Capability(P,S)_CT.count)
AS loglikelihood
FROM MDB.Capability(P,S)_CPT
NATURAL JOIN CDB.Capability(P,S)_CT
```

It is possible to extend the model manager to handle the multi-net structure learning method of the learn-and-join algorithm [26]. The algorithm learns multiple Bayesian networks and propagates edges among them. The *MDB* schema is easily extended to store multiple Bayesian networks in a single table. The edge propagation can be executed by the RDBMS using the view mechanism. For more details, please see [24].

This completes our description of how the modules of FACTORBASE are implemented using SQL. We next show how these modules support a key learning task: computing the predictions of an SRL model on a test instance.

## VI. TEST SET PREDICTIONS

Computing probabilities over the label of a test instance is important for several tasks. 1) Classifying the test instance, which is one of the main applications of a machine learning system for end users. 2) Comparing the class labels predicted against true class labels is a key step in several approaches to model scoring [14]. 3) Evaluating the accuracy of a machine learning algorithm by the train-and-test paradigm, where the system is provided a training set for learning and then we test its predictions on unseen test cases. We first discuss how to compute a prediction for a single test case, then how to compute an overall prediction score for a set of test cases. Class probabilities can be derived from Equation 1 as follows [14, Sec.2.2.2]. Let  $Y$  denote a ground par-RV to be classified, which we refer to as the **target variable**. For example, a ground atom may be *Intelligence(jack)*. In this example, we refer to jack as the **target entity**. Write  $\mathbf{X}_{-Y}$  for a database instance that specifies the values of all ground par-RVs, except for the target, which are used to predict the target node. Let  $[\mathbf{X}_{-Y}, y]$  denote the completed database instance where the target node is assigned value  $y$ . The log-linear model uses the likelihood  $P([\mathbf{X}_{-Y}, y])$  as the joint score of the label and the predictive features. The conditional probability is proportional to this score:

$$P(y|\mathbf{X}_{-Y}) \propto P([\mathbf{X}_{-Y}, y]) \quad (2)$$

where the joint distribution on the right-hand side is defined by Equation 1, and the scores of the possible class labels need to be normalized to define conditional probabilities.

*SQL Implementation.* The obvious approach to computing the log-linear score would be to use the likelihood computation of Section V-C for the entire database. This is inefficient because only instance counts that involve the target entity change the classification probability. This means that we need only consider query instantiations that match the appropriate logical variable with the target entity (e.g.,  $\mathbb{S} = jack$ ).

For a given set of random variables, target entity instantiation counts can be represented in a contingency table that we call the **target contingency table**. Figure 8 shows the format of a contingency table for target entities jack resp. jill.

jack\_Capability\_(P,S)\_CT

sid	Count	Cap.(P,S)	RA(P,S)	Salary(P,S)
Jack	5	N/A	N/A	F
Jack	5	4	high	T
....	....	....	....	....

jill\_Capability\_(P,S)\_CT

sid	Count	Cap.(P,S)	RA(P,S)	Salary(P,S)
Jill	3	N/A	N/A	F
Jill	7	4	high	T
...	....	....	....	....

Figure 8. Target contingency tables for target = jack and for target = jill.

Assuming that for each node with ID @parRVID@, a target contingency table named  $CDB.target\_@parRVID@\_CT$  has been built in the Count Database  $CDB$ , the log-likelihood SQL is as in Section V-C. For instance, the contribution of the  $Capability(\mathbb{P}, \mathbb{S})$  family is computed by the SQL query shown, but with the contingency table  $jack\_Capability(P,S)_CT$  in place of  $Capability(P,S)_CT$ . The new problem is finding the target contingency table. SQL allows us to solve this easily by restricting counts to the target entity in the WHERE clause. To illustrate, suppose we want to modify the contingency table query of Figure 6 to compute the contingency table for  $\mathbb{S} = jack$ . We add the student id to the SELECT clause, and the join condition  $S.s\_id = jack$  to the WHERE clause; see Table IV. The FROM clause is the same as in Figure 6. The metaquery of Figure 6 is easily changed to produce these SELECT and WHERE clauses.

Next consider a setting where a model is to be scored against an entire test set. For concreteness, suppose the problem is to predict the intelligence of a set of students  $Intelligence(jack)$ ,  $Intelligence(jill)$ ,  $Intelligence(student_3)$ , ...,  $Intelligence(student_m)$ . SQL supports *block access* where we process the test instances as a block. Intuitively, instead of building a contingency table for each test instance, we build a single contingency table that stacks together the individual contingency tables (Figure 8). Blocked access can be implemented in a beautifully simple manner in SQL: we simply add the primary key id field for the target entity to the GROUP BY list; see Table IV.

## VII. EVALUATION

Our experimental study describes how FACTORBASE can be used to implement a challenging machine learning application: Constructing a Bayesian network model for a relational database. Bayesian networks are a good illustration of typical challenges and how RDBMS capabilities can address them because: (1) Bayesian networks are widely regarded as a very useful model class in machine learning and AI, that supports decision making and reasoning under uncertainty. At the same time, they are considered challenging to learn from data. (2) Database researchers have proposed Bayesian networks for combining databases with uncertainty [30]. (3) A Bayesian network with par-RVs can be easily converted to other first-order representations, such as a Markov Logic Network; see [4].

We describe the system and the datasets we used. Code was written in MySQL Script and Java, JRE 1.7.0. and executed with 8GB of RAM and a single Intel Core 2 QUAD Processor Q6700 with a clock speed of 2.66GHz (no hyper-threading). The operating system was Linux Centos 2.6.32. The MySQL Server version 5.5.34 was run with 8GB of RAM and a single core processor of 2.2GHz. All code and datasets are available on-line [24].

### A. Datasets

We used six benchmark real-world databases. For detailed descriptions and the sources of the databases, please see [24] and the references therein. Table V summarizes basic information about the benchmark datasets. IMDb is the largest dataset in terms of number of total tuples (more than 1.3M tuples) and schema complexity. It combines the MovieLens database<sup>3</sup> with data from the Internet Movie Database (IMDb)<sup>4</sup> following [22].

TABLE V. DATASETS CHARACTERISTICS. #TUPLES = TOTAL NUMBER OF TUPLES OVER ALL TABLES IN THE DATASET.

Dataset	#Relationship Tables/ Total	# par-RV	#Tuples
MovieLens	1 / 3	7	1,010,051
Mutagenesis	2 / 4	11	14,540
UW-CSE	2 / 4	14	712
Mondial	2 / 4	18	870
Hepatitis	3 / 7	19	12,927
IMDb	3 / 7	17	1,354,134

Table V provides information about the number of par-RVs generated for each database. More complex schemas generate more random variables.

### B. Bayesian Network Learning

For learning the structure of a first-order Bayesian network, we used FACTORBASE to implement the previously existing learn-and-join algorithm (LAJ). The model search strategy of the LAJ algorithm is an iterative deepening search for

<sup>3</sup>www.grouplens.org, 1M version

<sup>4</sup>www.imdb.com, July 2013

TABLE IV. SQL QUERIES FOR COMPUTING TARGET CONTINGENCY TABLES SUPPORTING TEST SET PREDICTION.  $\langle$ ATTRIBUTE-LIST $\rangle$  AND  $\langle$ KEY-EQUALITY-LIST $\rangle$  ARE AS IN FIGURE 6.

Access	SELECT	WHERE	GROUP BY
Single	COUNT(*) AS count, $\langle$ Attribute-List $\rangle$ , S.sid	$\langle$ Key-Equality-List $\rangle$ AND S.s_id = jack	$\langle$ Attribute-List $\rangle$
Block	COUNT(*) AS count, $\langle$ Attribute-List $\rangle$ , S.sid	$\langle$ Key-Equality-List $\rangle$	$\langle$ Attribute-List $\rangle$ , S.sid

correlations among attributes along longer and longer chains of relationships. For more details please see [26]. The previous implementation of the LAJ algorithm posted at [24], limits the par-factors so they contain at most *two* relationship par-RVs; FACTORBASE overcomes this limitation.

A major design decision is how to make sufficient statistics available to the LAJ algorithm. In our experiments we followed a *pre-counting* approach where the count manager constructs a **joint contingency table** for *all* par-RVs in the random variable database. An alternative would be *on-demand* counting, which computes many contingency tables, but only for factors that are constructed during the model search [17]. Pre-counting is a form of data preprocessing: Once the joint contingency table is constructed, local contingency tables can be built quickly by summing (Group By). Different structure learning algorithms can therefore be run quickly on the same joint contingency table. For our evaluation, pre-counting has several advantages. (1) Constructing the joint contingency table presents a maximally challenging task for the count manager. (2) Separating counting/data access from model search allows us to assess separately the resources required for each task.

### C. Results

Table VI reports the number of sufficient statistics for constructing the joint contingency table. This number depends mainly on the number of par-RVs. The number of sufficient statistics can be quite large, over 15M for the largest dataset IMDB. Even with such large numbers, constructing contingency tables using the SQL metaqueries is feasible, taking just over 2 hours for the very large IMDB set. The number of Bayesian network parameters is much smaller than the number of sufficient statistics. The difference between the number of parameters and the number of sufficient statistics measures how compactly the BN summarizes the statistical information in the data. Table VI shows that Bayesian networks provide very compact summaries of the data statistics. For instance for the Hepatitis dataset, the ratio is  $12,374,892/569 > 20,000$ . The IMDB database is an outlier, with a complex correlation pattern that leads to a dense Bayesian network structure.

TABLE VI. COUNT MANAGER: SUFFICIENT STATISTICS AND PARAMETERS

Dataset	# Database Tuples	# Sufficient Statistics (SS)	SS Computing Time (s)	#BN Parameters
Movielens	1,010,051	252	2.7	292
Mutagenesis	14,540	1,631	1.67	721
UW-CSE	712	2,828	3.84	241
Mondial	870	1,746,870	1,112.84	339
Hepatitis	12,927	12,374,892	3,536.76	569
IMDb	1,354,134	15,538,430	7,467.85	60,059

Table VII shows that the graph structure of a Bayesian network contains a small number of edges relative to the

number of parameters. The parameter manager provides fast maximum likelihood estimates for a given structure. This is because computing a local contingency table for a BN family is fast given the joint contingency table.

TABLE VII. MODEL MANAGER EVALUATION.

Dataset	# Edges in Bayes Net	# Bayes Net Parameters	Parameter Learning Time (s)
Movielens	72	292	0.57
Mutagenesis	124	721	0.98
UW-CSE	112	241	1.14
Mondial	141	339	60.55
Hepatitis	207	569	429.15
IMDb	195	60,059	505.61

Figure 9 compares computing predictions on a test set using an instance-by-instance loop, with a separate SQL query for each instance, vs. a single SQL query for all test instances as a block (Table IV). Table VIII specifies the number of test instances for each dataset. We split each benchmark database into 80% training data, 20% test data. The test instances are the ground atoms of all descriptive attributes of entities. The blocked access method is 10-100 faster depending on the dataset. The single access method did not scale to the large IMDB dataset (timeout after 12 hours).

TABLE VIII. # OF TEST INSTANCES

Dataset	Movielens	Mutagenesis	UW-CSE	Mondial	Hepatitis	IMDb
#instance	4,742	3,119	576	505	2,376	46,275

Figure 9. Times (s) for Computing Predictions on Test Instances. The right red column shows the time for looping over single instances using the Single Access Query of Table IV. The left blue column shows the time for the Blocked Access Query of Table IV.

Table IX reports result for the complete learning of a Bayesian network, structure and parameters. It benchmarks

FACTORBASE against functional gradient boosting, a state-of-the-art multi-relational learning approach. MLN\_Boost learns a Markov Logic Network, and RDN\_Boost a Relational Dependency Network. We used the BoostR implementation [13]. To make the results easier to compare across databases and systems, we divide the total running time by the number of par-RVs for the database (Table V). Table IX shows that structure learning with FACTORBASE is fast: even the large complex database IMDb requires only around 8 minutes/par-RV. Compared to the boosting methods, FACTORBASE shows excellent scalability: neither boosting method terminates on the IMDb database, and while RDN\_Boost terminates on the MovieLens database, it is almost 5,000 times slower than FACTORBASE. Much of the speed of our implementation is due to quick access to sufficient statistics. As the last column of Table IX shows, on the larger datasets FACTORBASE spends about 80% of computation time on gathering sufficient statistics via the count manager. This suggests that a large speedup for the boosting algorithms could be achieved if they used the FACTORBASE in-database design.

We do not report accuracy results due to space constraints and because predictive accuracy is not the focus of this paper. On the standard conditional log-likelihood metric, as defined by Equation 2, the model learned by FACTORBASE performs better than the boosting methods on all databases. This is consistent with the results of previous studies [26].

TABLE IX. LEARNING TIME COMPARISON (SEC) WITH OTHER STATISTICAL-RELATIONAL LEARNING SYSTEMS. NT = NON-TERMINATION

Dataset	RDN_Boost	MLN_Boost	FB-Total	FB-Count
MovieLens	5,562	N/T	1.12	0.39
Mutagenesis	118	49	1	0.15
UW-CSE	15	19	1	0.27
Mondial	27	42	102	61.82
Hepatitis	251	230	286	186.15
IMDb	N/T	N/T	524.25	439.29

*Conclusion.* FACTORBASE leverages RDBMS capabilities for scalable management of statistical analysis objects. It efficiently constructs and stores large numbers of sufficient statistics and parameter estimates. The RDBMS support for statistical-relational learning translates into orders of magnitude improvements in speed and scalability.

## VIII. RELATED WORK

The design space for combining machine learning with data management systems offers a number of possibilities, several of which have been explored in previous and ongoing research. We selectively review the work most relevant to our research. Figure 10 provides a tree structure for the research landscape.

### A. Single-Table Machine Learning

Most machine learning systems, such as Weka or R, support learning from a single table or data matrix only. The single-table representation is appropriate when the data points represent a homogeneous class of entities with similar attributes, where the attributes of one entity are independent of those of others [14]. The only way a single-table system can be applied

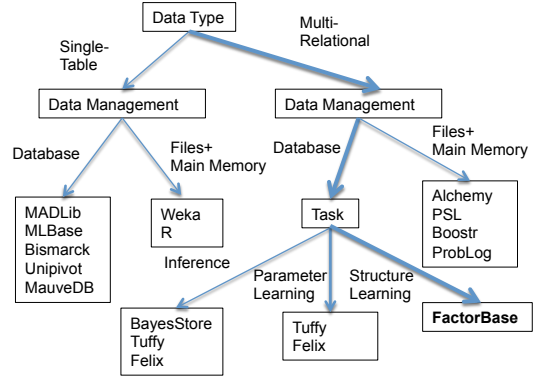

Figure 10. A tree structure for related work in the design space of machine learning  $\times$  data management

to multi-relational data is after a preprocessing step where multiple interrelated tables are converted to a single data table. When the learning task is classification, such preprocessing is often called propositionalization [14]. This “flattening” of the relational structure typically involves a loss of information.

1) *RDBMS Learning:* Leveraging RDBMS capabilities through SQL programming is the unifying idea of the recent MADLib framework [11]. An advantage of the MADLib approach that is shared by FACTORBASE is that in-database processing avoids exporting the data from the input database. The Apache Spark [2] framework includes MLBase and Spark-SQL that provide support for distributed processing, SQL, and automatic refinement of machine learning algorithms and models [15]. Other RDBMS applications include gathering sufficient statistics [9], and convex optimization [6]. The MauveDB system [3] emphasizes the importance of several RDBMS features for combining statistical analysis with databases. As in FACTORBASE, this includes storing models and associated parameters as objects in their own right, and using the view mechanism to update statistical objects as the data change. A difference is that MauveDB presents model-based views of the *data* to the user, whereas FACTORBASE presents views of the *models* to machine learning applications.

2) *RDBMS Inference:* Wong *et al.* applied SQL operators such as the natural join to perform log-linear inference with a single-table graphical model [32] stored in an RDBMS. Monte Carlo methods have also been implemented with an RDBMS to perform inference with uncertain data [12], [31]. The MCDB system [12] stores parameters in database tables like FACTORBASE.

### B. Multi-Relational Learning

For overviews of multi-relational learning please see [7], [4], [14]. Most implemented systems, such as Aleph and Alchemy, use a logic-based representation of data derived from Prolog facts, that originated in the Inductive Logic Programming community [5].

1) *RDBMS Learning:* The ClowdFlows system [16] allows a user to specify a MySQL database as a data source, then

converts the MySQL data to a single-table representation using propositionalization. Singh and Graepel [28] present an algorithm that analyzes the relational database system catalog to generate a set of nodes and a Bayesian network structure. This approach utilizes SQL constructs as a data description language in a way that is similar to our Schema Analyzer. Differences include the following. (1) The Bayesian network structure is fixed and based on latent variables, rather than learned for observable variables only, as in our case study. (2) The RDBMS is not used to support learning after random variables have been extracted from the schema.

Qian *et al.* [25] discuss work related to the contingency table problem and introduce contingency table algebra. Their paper focuses on a Virtual Join algorithm for computing sufficient statistics that involve negated relationships. They do not discuss integrating contingency tables with other structured objects for multi-relational learning.

2) *RDBMS Inference*: Database researchers have developed powerful probabilistic inference algorithms for multi-relational models. The BayesStore system [30] introduced the principle of treating all statistical objects as first-class citizens in a relational database as FACTORBASE does. The Tuffy system [20] achieves highly reliable and scalable inference for Markov Logic Networks (MLNs) with an RDBMS. It leverages inference capabilities to perform MLN parameter learning. RDBMS support for local search parameter estimation procedures, rather than closed-form maximum-likelihood estimation, has also been explored [6], [20], [21].

## IX. CONCLUSION AND FUTURE WORK

Compared to traditional learning with a single data table, learning for multi-relational data requires new system capabilities. In this paper we described FACTORBASE, a system that leverages the existing capabilities of an SQL-based RDBMS to support statistical-relational learning. Representational tasks include specifying metadata about structured first-order random variables, and storing the structure of a learned model. Computational tasks include storing and constructing sufficient statistics, and computing parameter estimates and model selection scores. We showed that SQL scripts can be used to implement these capabilities, with multiple advantages. These advantages include: 1) Fast program development through high-level SQL constructs for complex table and count operations. 2) Managing large and complex statistical objects that are too big to fit in main memory. For instance, some of our benchmark databases require storing and querying millions of sufficient statistics. While FACTORBASE provides good solutions for each of these system capabilities in isolation, the ease with which large complex statistical-relational objects can be integrated via SQL queries is a key feature. Because information about random variables, sufficient statistics, and models is all represented in relational database tables, a machine learning application can access and combine the information in a uniform way via SQL queries.

Empirical evaluation on six benchmark databases showed significant scalability advantages from utilizing the RDBMS capabilities: Both structure and parameter learning scaled well

to millions of data records, beyond what previous multi-relational learning systems can achieve.

*Future Work*. Further potential application areas for FACTORBASE include managing massive numbers of aggregate features for classification [23], and collective matrix factorization [27], [28]. While our implementation has used simple SQL plus indexes, there are opportunities for optimizing RDBMS operations for the workloads required by statistical-relational structure learning. These include view materialization and the key scalability bottleneck of computing multi-relational sufficient statistics. NoSQL databases can exploit a flexible data representation for scaling to very large datasets. However, SRL requires count operations for random complex join queries, which is a challenge for less structured data representations. An important goal is a single RDBMS package for both learning and inference that integrates FACTORBASE with inference systems such as BayesStore and Tuffy. There are several fundamental system design choices whose trade-offs for SRL warrant exploration. These include the choice between pre-counting and post-counting sufficient statistics, and using main memory vs. RDBMS disk storage. For instance, model selection scores can be cached in either main memory or the database. Our SQL-based approach facilitates using distributed computing systems such as SparkSQL [1], which have shown great potential for scalability. In sum, we believe that the successful use of SQL presented in this paper shows that relational algebra can play the same role for multi-relational learning as linear algebra for single-table learning: a unified language for both representing statistical objects and for computing with them.

## ACKNOWLEDGEMENT

This research was supported by a Discovery grant to Oliver Schulte by the Natural Sciences and Engineering Research Council of Canada. Zhensong Qian was supported by a grant from the China Scholarship Council. A position paper based on this work was presented at the StarAI 2015 workshop. We thank the workshop reviewers and participants for helpful comments.
